EARLY ONLINE RELEASE

This is a preliminary PDF of the author-produced manuscript that has been peer-reviewed and accepted for publication. Since it is being posted so soon after acceptance, it has not yet been copyedited, formatted, or processed by AMS Publications. This preliminary version of the manuscript may be downloaded, distributed, and cited, but please be aware that there will be visual differences and possibly some content differences between this version and the final published version.

The DOI for this manuscript is doi: 10.1175/JCLI-D-12-00113.1

The final published version of this manuscript will replace the preliminary version at the above DOI once it is available.

If you would like to cite this EOR in a separate work, please use the following full citation:

Abstract

1
2
3
4 The precursor signals of convection initiation associated with the Madden-Julian Oscillation
5 (MJO) in boreal winter were investigated through the diagnosis of the ERA-40 reanalysis for the
6 period of 1982-2001. The western equatorial Indian Ocean (WIO) is a key region of the MJO
7 initiation. A marked increase of specific humidity and temperature in the lower troposphere
8 appears 5-10 days prior to the convection initiation. The increased moisture and temperature
9 causes a convectively more unstable stratification, leading to the onset of convection.

10 A diagnosis of lower-tropospheric moisture (heat) budgets shows that the moisture
11 (temperature) increase is caused primarily by the horizontal advection of the mean specific
12 humidity (temperature) by the MJO flow. The anomalous flow is primarily determined by the
13 downstream Rossby wave response to a preceding suppressed-phase MJO over the eastern Indian
14 Ocean, whereas the upstream Kelvin wave response to the previous eastward-propagating
15 convective-phase MJO is not critical. An idealized numerical experiment further supports this
16 claim.

17 The Southern Hemisphere (SH) mid-latitude Rossby wave train and associated wave
18 activity flux prior to the MJO initiation were diagnosed. It is found that SH mid-latitude Rossby
19 waves may contribute to MJO initiation over the western Indian Ocean through wave energy
20 accumulation. Idealized numerical experiments confirm that SH mid-latitude perturbations play
21 an important role in affecting the MJO variance in the tropics. A barotropic energy conversion
22 diagnosis indicates that there is continuous energy transfer from the mean flow to intraseasonal
23 disturbances over the initiation region, which may help trigger MJO development.

1 **1. Introduction**

2 The tropical intraseasonal oscillation (ISO), also called Madden–Julian oscillation (MJO), is
3 one of dominant atmospheric low-frequency modes in the tropics. It is characterized by the
4 eastward propagation of large-scale convection and zonal wind along the equator in boreal
5 winter, with a typical 20-90-day periodicity and a planetary zonal scale (Madden and Julian 1971,
6 1972, 1994; Li and Zhou 2009). An unsolved question regarding its life cycle is how MJO is
7 initiated over the western equatorial Indian Ocean (WIO).

8 A number of theories have been advanced in understanding the initiation of the MJO. These
9 theories may be classified according to an internal (tropical) or an external (extratropical) origin.
10 The tropical origin hypotheses include the forcing from upstream (i.e., west of the initiation
11 region) related to a previous MJO event that circumnavigates around the global tropics (e.g., Lau
12 and Peng 1987; Wang and Li 1994; Matthews 2000, 2008; Seo and Kim 2003) and processes due
13 to local changes in air-sea fluxes and underlying SST (e.g., Li et al. 2008), planetary boundary
14 layer (PBL) moisture and convergence (Kemball-Cook and Weare 2001; Jiang and Li 2005), or
15 cloud-radiation-moisture feedbacks (Bladé and Hartmann 1993; Hu and Randall 1994; Raymond
16 2000; Sobel and Gildor 2003; Zhang and Song 2009; Maloney et al. 2010). The promise behind
17 the circumnavigating theory is that the eastward-propagating MJO wave may trigger deep
18 convection over moist and warm Indian Ocean after it passes the African continent, with possible
19 topographic lifting effect (Hsu and Lee 2005). In this scenario, the forcing from the upstream
20 (west of the initiation region) holds a key for triggering new convection over the WIO. Different
21 from this upstream forcing scenario, Jiang and Li (2005) proposed a downstream forcing
22 scenario, in which a negative MJO heating over the eastern equatorial Indian Ocean (EIO) may
23 initiate an opposite-phase MJO in the WIO. The change of the PBL moisture was attributed to

1 anomalous ascending (or descending) motion induced by temperature advection. Bladé and
2 Hartmann (1993) and Hu and Randall (1994) suggested that the initiation of convection in the
3 tropical Indian Ocean is a result of self-adjustment of a stationary heat source by nonlinear
4 interactions among radiation, convection and surface moisture flux between active and inactive
5 convection regimes. Li et al. (2008) suggested that cold SST anomalies induced by an
6 eastward-propagating active-phase MJO may exert a delayed feedback to the subsequent,
7 opposite-phase MJO.

8 The extratropical origin hypotheses emphasized forcing from mid-latitude perturbations
9 including the energy dispersion or the momentum transport of mid-latitude Rossby waves and
10 mid-latitude baroclinic eddies (e.g., Hsu et al. 1990; Bladé and Hartmann 1993; Matthews and
11 Kiladis 1999; Slingo et al. 1999; Lin et al. 2000; Pan and Li 2007; Lin et al. 2007; Ray et al.
12 2009). For example, Hsu et al. (1990) suggested a triggering effect by extratropical perturbations
13 on tropical convection based on a case study. Kiladis and Weickmann (1992) showed that the
14 extratropical Rossby wave trains propagating into the Tropics from mid-latitude played a role in
15 organizing MJO convection.

16 Most of the studies above were based on either a theoretical model with simplified dynamic
17 framework or a case study. The present study is aimed to reveal precursor signals and processes
18 associated with MJO initiation based on the diagnosis of 20-year observational and reanalysis
19 data. From a microscopic view, we will examine the local moisture and heat budgets to reveal
20 specific processes that give rise to the convection initiation over the WIO. From a macroscopic
21 view, we will further investigate the relative importance of upstream versus downstream
22 processes and extratropical versus tropical forcing effects. The rest of this paper is organized as
23 follows. The datasets and methods employed in this study are presented in section 2. In section 3,

1 we reveal the precursor dynamic and thermodynamic signals of the MJO initiation. Then a
2 lower-tropospheric moisture and heat budget analysis is followed in sections 4. In section 5, the
3 upstream and downstream forcing effect is further examined. In section 6, we investigate
4 possible mid-latitude impacts through the diagnosis of wave activity flux convergence and
5 idealized numerical experiments. Finally, the conclusion and discussion are given in the last
6 section.

7

8 **2. Data, methods and numerical experiments**

9 **a. Data**

10 The primary datasets used for this study are the National Oceanic and Atmospheric
11 Administration (NOAA) outgoing longwave radiation (OLR; Liebmann and Smith 1996) and the
12 European Centre for Medium-Range Weather Forecast (ECMWF) Re-Analysis (ERA-40; Uppala
13 et al. 2005). All the datasets have a horizontal resolution of $2.5^\circ \times 2.5^\circ$. The OLR is used as a
14 proxy for deep convection in the tropics. The ERA-40 reanalysis data include multiple-level
15 horizontal velocity, vertical velocity, specific humidity, temperature and geopotential height. In
16 this study, we focus on the MJO behavior in northern winter (November - April) for the period of
17 1982-2001.

18

19 **b. Analysis methods**

20 An EOF analysis was employed to extract the dominant modes of MJO convection. Before
21 performing the EOF analysis, daily OLR and other atmospheric variables including 3D wind,
22 geopotential height, specific humidity and temperature during 1982-2001 were subject to a
23 20-90-day band-pass filtering based on harmonic decomposition (Kemball-Cook and Wang 2001;

1 Teng and Wang 2003; Jiang et al. 2004). The filtered OLR data from November to April each
 2 year were then used for the EOF analysis. The domain for the EOF analysis spans from 30°S to
 3 30°N and from 40°E to 180°E. The corresponding atmospheric wind, humidity and temperature
 4 patterns are derived based on the composite analysis of time series of the dominant EOF mode.

5 To understand the moisture and temperature changes associated with MJO initiation, both
 6 the moisture and heat budgets were calculated. According to Yanai et al. (1973), the temperature
 7 tendency at each constant pressure level is determined by the sum of horizontal temperature
 8 advection, adiabatic process associated with vertical motion, and the atmospheric apparent heat
 9 source, Q_1 . The moisture tendency at each constant pressure level is determined by the sum of
 10 horizontal and vertical moisture advection and the atmospheric apparent moisture sink, Q_2 . The
 11 temperature and moisture tendency equations may be written as

$$\frac{\partial T}{\partial t} = -V\nabla T + \omega \frac{RT}{c_p p} - \omega \frac{\partial T}{\partial p} + Q_1 / c_p \quad (1)$$

$$\frac{\partial q}{\partial t} = -V\nabla q - \omega \frac{\partial q}{\partial p} - \frac{Q_2}{L} \quad (2)$$

13 where c_p denotes the specific heat at constant pressure, R the gas constant, ∇ the horizontal
 14 gradient operator, L the latent heat of condensation, t time, p pressure, T temperature, q specific
 15 humidity, V horizontal velocity vector, and ω vertical p-velocity. $(RT/c_p p) - (\partial T/\partial p)$ represents
 16 the static stability. Note that Q_1 represents the total diabatic heating including radiation, latent
 17 heating, surface heat flux, and subgrid-scale processes; Q_2 represents the latent heating due to
 18 condensational or evaporational processes in the atmosphere and subgrid-scale moisture flux
 19 convergence (Yanai et al. 1973). Applying a 20-90-day band-pass filtering operator to the
 20 equations above and integrating each term vertically from the surface (1000hPa) to 700 hPa, one
 21 may derive the intraseasonal low-tropospheric moisture and heat budget equations.

c. Numerical experiments

The atmospheric general circulation model (AGCM) used in the study is ECHAM version 4.6 (hereafter ECHAM4), which was developed by the Max Planck Institute for Meteorology (MPI; Roeckner et al. 1996). The model was run at a horizontal resolution of spectral triangular 42 (T42), roughly equivalent to 2.8 latitude×2.8 longitude, with 19 vertical levels in a hybrid sigma-pressure coordinate system extending from surface to 10 hPa. ECHAM4 is one of the best AGCMs in the simulation of MJO (Lin et al. 2006), and it has been used in studying the role of air-sea interaction on MJO (Fu et al. 2002), northward propagation of boreal summer ISO (Jiang et al. 2004) and MJO predictability (Fu et al. 2009).

To identify the relative contributions of the circumnavigating MJO mode and the mid-latitude forcing effect in triggering MJO convection, we design a set of sensitivity experiments. In the control experiment, the model is forced by the climatological monthly SST. In the first sensitivity experiment (termed as “EXP_TA”), a strong Newtonian-type damping is applied to force the model prognostic variables (such as u , v , q , T) toward the model climatologic annual cycle retrieved from the control run over the tropical Atlantic (20°S-20°N, 60°W-20°E) region. By doing so, the mean state over the tropical Atlantic region remains the same while intraseasonal and higher-frequency variability is greatly suppressed. Through this experiment, we intentionally suppress the circumnavigating MJO mode. The difference of the MJO variance between the control run and EXP_TA may reflect how strong the effect of the upstream forcing is on the MJO initiation.

1 In the second sensitivity experiment (termed as “EXP_NS”), similar Newtonian damping is
2 applied over two latitudinal zones, 20°S-30°S and 20°N-30°N, to force the model prognostic
3 variables toward the controlled climatologic annual cycle. By doing so, the intraseasonal and
4 higher-frequency variability over the transitional zones is greatly suppressed and
5 tropics-midlatitude connection is broken. As a result, the mid-latitude influence on the tropical
6 MJO variability is intentionally suppressed. The difference between the control and the EXP_NS
7 run illustrates how strong the effect of the mid-latitude forcing is on the MJO variability.

8 To distinguish the Southern Hemisphere (SH) and Northern Hemisphere (NH) forcing
9 effect, the sensitivity experiments (termed as “EXP_SH” and “EXP_NH”) were conducted. In
10 EXP_SH (EXP_NH) run, the same Newtonian damping approach was only applied to the SH
11 (NH) latitudinal zone, 20°S-30°S (20°N-30°N). By doing so, the SH (NH) mid-latitude influence
12 on the tropical MJO variability is suppressed. The differences between the EXP_SH run and the
13 EXP_NH run illustrate the relative contribution of the SH and NH mid-latitude forcing on the
14 tropical MJO variability. Table 1 lists all these numerical experiments.

15

16 **3. Dynamic and thermodynamic precursor signals prior to MJO initiation**

17 Many previous studies identified MJO signals using a linear principal component analysis
18 in a global tropics domain (e.g., Maloney and Hartmann 1998; Kessler 2001; Wheeler and
19 Hendon 2004). To clearly identify processes associated with MJO initiation, a regional EOF
20 analysis was employed over the Indo-Pacific warm pool region. The EOF analysis of the
21 intraseasonal OLR anomaly reveals two dominant patterns in northern winter (Fig. 1a, b). The
22 first EOF mode accounts for about 12% of the total variance. The most conspicuous feature of
23 this mode is a seesaw in convection over the tropical Indian Ocean and the tropical western

1 Pacific. The second EOF mode (Fig. 1b) explains about 10% of the total variance. This mode
2 shows a suppressed convection center over the Maritime Continent. Figure 1c shows that the
3 time series of the two leading EOF modes are significantly correlated. Thus, the two modes
4 reflect the eastward propagating MJO mode at different phases. The maximum positive
5 correlation occurs around -10 day, implying that the second mode leads the first mode by 10
6 days.

7 The time series of the first EOF mode was used to select strong MJO events for the
8 subsequent composite analysis. Here the strong MJO events are identified by the amplitude of
9 the first principal component exceeding one standard deviation, as indicated by the horizontal
10 dashed lines in Fig. 1d. During the 20-yr period, 55 cases with strong negative OLR center
11 located over the EIO were selected. On the average, it is about 3 MJO cases each winter.
12 Composite OLR evolution patterns were derived based on the 55 events, with a reference day
13 (day 0) corresponding to each peak above the one standard deviation line in Fig. 1d. Thus, day 0
14 represents the time when an enhanced MJO convection center appears over the EIO.

15 To reveal the key initiation region in the Indian Ocean, we examine both the maximum ISO
16 variance map and the composite OLR evolution map. Figure 2 shows the maximum OLR
17 variance pattern associated with MJO in northern winter. It is clear that the maximum variability
18 of MJO convective activity in the WIO appears south of the equator. This is understandable
19 because the seasonal mean convection is also located south of the equator in boreal winter (e.g.,
20 Hsu and Li 2012). Figure 3 illustrates the composite evolution of OLR from day -9 to day 0 at a
21 3-day interval. The composite OLR at day 0 resembles the first EOF mode pattern, as expected.
22 The OLR evolution maps reveal that the MJO convection was firstly initiated in the southwestern

1 Indian Ocean, and then it propagates eastward. During its eastward journey, the convection is
2 strengthened and shifts more toward the equator.

3 Based on the MJO variance and evolution maps, the region of (20°S-0°N, 50°E-70°E) is
4 defined as the MJO convection initiation region. To reveal precursor signals associated with the
5 convection initiation, we examine the time evolution of several key atmospheric variables
6 averaged over the region. Figure 4a presents the time evolution of the intraseasonal OLR
7 anomaly averaged over (20°S-0°N, 50°E-70°E). Note that the OLR anomaly transitions from a
8 positive to a negative value at day -15. Consistent with the OLR transition is the switch of sign
9 of the mid-tropospheric vertical motion, from an anomalous descending motion to an anomalous
10 ascending motion (Fig. 4b). Thus day -15 is regarded as the initiation date.

11 It is interesting to note that 5-10 days prior to the initiation date, a marked sign change of
12 the specific humidity and temperature fields appears in the lower troposphere (Fig. 4c and d),
13 that is, the lower-tropospheric specific humidity and temperature anomalies transition from a
14 negative value to a positive value one week prior to the initiation date. The specific humidity
15 perturbation is initially confined at low level and gradually penetrates into the middle
16 troposphere. At day -15, the positive moisture anomaly has extended up to 500 hPa. The
17 temperature perturbation, on the other hand, is primarily confined below 700 hPa till day -8.

18 The marked increase of both the lower-tropospheric specific humidity and temperature
19 leads to an increase of equivalent potential temperature (θ_e) and moist static energy (MSE) in the
20 lower troposphere, as shown in Fig. 4e and f. The vertical time cross section of θ_e shows that
21 about one week prior to the initiation date, a positive θ_e perturbation appears in the lower
22 troposphere. This positive perturbation intensifies rapidly while extending upward, closely
23 following the specific humidity evolution.

1 Considering the wide range of temporal spectrum of the MJO signal, we conducted a
2 sensitivity test by making MJO composite analysis based on phase, not lagged day. Each of
3 individual MJO events was separated into 13 phases (on average 4 days per phase) from 0° to
4 360° at an interval of 30°. A similar low-tropospheric moisture and temperature precursor signal
5 is found about 8 days prior to convection initiation (figure not shown). Thus the phase composite
6 result is consistent with the lagged-day composite result.

7 The greater increase of low-level θ_e may potentially lead to a convectively more unstable
8 stratification. We introduced a potential instability parameter that is defined as the difference of
9 equivalent potential temperature between the lower troposphere (1000-700 hPa) and the mid-
10 troposphere (400-300 hPa):

$$11 \qquad \qquad \qquad \Delta\theta_e = \theta_{eL|1000-700hPa} - \theta_{eM|400-300hPa} \qquad \qquad \qquad (3)$$

12 where θ_{eL} denotes the averaged θ_e over 700-1000 hPa, θ_{eM} represents the averaged θ_e over 300-
13 400 hPa. A positive (negative) $\Delta\theta_e$ implies that the atmosphere is more (less) convectively
14 unstable. The time evolution of $\Delta\theta_e$ shows that the instability parameter increases rapidly from
15 day -25 to day -15 (Fig. 5a). The marked increase is primarily attributed to the increase of
16 lower-tropospheric equivalent potential temperature, while the equivalent potential temperature
17 in the mid-troposphere does not change much during the period. This implies that the increase of
18 the lower-tropospheric moisture and temperature preconditions a convectively more unstable
19 stratification, which eventually leads to the initiation of the MJO convection.

20 Next we examine what processes contribute to the increase of low-level moisture and
21 temperature prior to the initiation date. As shown in Fig. 4, both the moistening and warming in
22 the lower troposphere occur one week prior to the initiation date. Such the moistening and
23 warming may build up local moist static energy and favor for the generation of new convection.

1 To quantitatively measure the relative contribution of the moistening and warming to the $\Delta\theta_e$
2 increase from day -25 to day -15, we conducted the following two calculations. Firstly we kept
3 the specific humidity constant on the intraseasonal timescale while allowing the temperature to
4 change realistically. Secondly we kept the temperature constant while allowing the humidity to
5 vary. The result shows that the specific humidity change plays a more important role, and it
6 contributes to about 75% of the $\Delta\theta_e$ change (Fig. 5b). This points out that the preconditioning of
7 moisture is crucial for MJO convection initiation, whereas the increase of lower-tropospheric
8 temperature also plays a role.

9

10 **4. Moisture and heat budget diagnoses**

11 The analysis above indicates that lower-tropospheric moistening and warming prior to the
12 convection initiation is crucial for the establishment of a convectively more unstable
13 stratification. What physical processes contribute to the lower-tropospheric moistening and
14 warming? In this section, both the lower-tropospheric moisture and heat budgets are diagnosed,
15 in order to address this question.

16 Figure 6 shows the diagnosis result from vertically-integrated (from 1000 hPa to 700 hPa)
17 intraseasonal moisture budget terms. It is clear that the positive moisture tendency during the
18 initiation period (from day -25 to -15) is mainly attributed to the horizontal advection, while the
19 vertical advection (due to subsidence and associated divergence) is against the lower-
20 tropospheric moistening. The result indicates that the lower-tropospheric moistening process
21 during the MJO initiation is very different from that during the MJO eastward propagation phase.
22 In the latter case the lower-tropospheric moistening is primarily attributed to the vertical
23 advection associated with PBL convergence (Hsu and Li 2012).

1 The apparent moisture source term ($-Q_2/L$) plays a minor but positive role in the
 2 low-tropospheric moistening. This is because anomalous descending motion during the initiation
 3 period reduces the mean precipitation, leading to less condensational heating and thus more
 4 moisture retained in the atmosphere. The surface latent heat flux anomaly, on the other hand,
 5 does not contribute to the moistening during the initiation period (Fig. 6c).

6 To examine specific horizontal advection processes that contribute to the
 7 lower-tropospheric moistening, both the specific humidity and wind fields are decomposed into
 8 three components, the low-frequency background state (LFBS, with a period longer than 90
 9 days), the intraseasonal (20-90-day) component, and the high-frequency (with a period less than
 10 20 days) component:

$$11 \quad q = \bar{q} + q' + q^*, \quad u = \bar{u} + u' + u^*, \quad v = \bar{v} + v' + v^* \quad (4)$$

12 where a bar, a prime and a star denote the LFBS, MJO and high-frequency component
 13 respectively.

14 Figure 6b shows the contributions from each of nine horizontal advection terms. The largest
 15 term comes from the advection of the mean moisture by the MJO flow ($-\bar{V}' \cdot \nabla \bar{q}$). The second
 16 largest term is the advection of anomalous moisture by the LFBS flow ($-\bar{V} \cdot \nabla q'$).

17 Figure 7a presents the horizontal patterns of the LFBS specific humidity field and the MJO
 18 wind perturbation field. Both the background specific humidity and anomalous wind fields were
 19 derived based on the time average from day -25 to day -15 and vertical integration from 1000
 20 hPa to 700 hPa. The maximum LFBS specific humidity is located along 10°S, where the
 21 seasonal mean convection is also strongest. Note that the MJO flow during the initiation period is
 22 dominated by anomalous easterlies and two anticyclonic Rossby gyres over the tropical Indian

1 Ocean. Such a wind anomaly resembles the Gill (1980) pattern and is typically observed when
2 the suppressed MJO convection is located in the EIO. A further examination of the intraseasonal
3 OLR field confirms that a maximum positive OLR center associated with MJO is indeed located
4 over the EIO during the period (Fig. 11). The anomalous winds advect the background high
5 moisture in such a way that they increases the lower-tropospheric moisture over the initiation
6 region (20°S-0°N, 50°E-70°E).

7 The advection of the perturbation moisture by the mean flow, particularly from the northern
8 boundary of the initiation domain, also contributes to the local moistening (Fig. 7b). A maximum
9 anomalous specific humidity center is located on the north edge of the initiation domain.
10 According to our calculation, this positive moisture anomaly is attributed to both the anomalous
11 horizontal advection and the apparent moisture source (figure not shown). The background wind
12 advects the anomalous moisture southward, leading to the increase of moisture in the initiation
13 region.

14 The calculation of vertically integrated (from 1000 hPa to 700 hPa) intraseasonal heat
15 budget shows that during the initiation period the positive temperature tendency is caused by
16 both the horizontal advection and the descending-induced adiabatic warming (Fig. 8a). The
17 diabatic heating, on the other hand, has a negative impact.

18 Similar to the moisture diagnosis, the air temperature and wind fields were decomposed into
19 the LFBS, the intraseasonal and the high-frequency components (i.e., $T = \bar{T} + T' + T^*$, $u = \bar{u} + u' + u^*$,
20 $v = \bar{v} + v' + v^*$). Figures 8b and 8c show that the largest contribution to the horizontal advection
21 arises from the advection of the background temperature by the MJO flow and the largest
22 contribution of the adiabatic warming arises from the anomalous descending motion. Other terms
23 are generally small.

1 Figure 9 presents the horizontal patterns of lower-tropospheric mean temperature and
2 anomalous wind fields averaged from day -25 to day -15. The maximum mean temperature
3 appears along 10°S. The anomalous warm advection by the MJO flow leads to the increase of the
4 lower-tropospheric temperature over the initiation region.

5

6 **5. Circumnavigating upstream forcing versus downstream forcing**

7 The moisture and heat budget analyses above reveals that the low-tropospheric moistening
8 and warming prior to the MJO initiation are attributed to the anomalous wind forcing over the
9 tropical Indian Ocean. A key issue then is what causes the generation of the anomalous wind.
10 There are two possible sources in generating the anomalous wind. Firstly, the anomalous
11 easterlies may be a direct Kelvin wave response to a positive MJO heating over western Pacific
12 (see a schematic diagram in Fig 10a). This is possible as the preceding MJO convection travels
13 eastward along the equator after initiated over the WIO. This represents an upstream forcing of
14 the circumnavigating MJO mode. Secondly, the anomalous wind over the tropical Indian Ocean
15 may be a direct Rossby wave response to a negative MJO heating over the EIO (see a schematic
16 diagram in Fig. 10b). This is possible because a suppressed-phase MJO emerges in the WIO after
17 a convective-phase MJO moves to the EIO; the suppressed-phase MJO then intensifies and
18 moves eastward. This scenario represents a downstream forcing of an opposite-phase MJO in the
19 EIO.

20 To illustrate what (upstream or downstream forcing effect) actually happens in real world,
21 we plotted the composite OLR and 850-hPa wind evolution maps from day -25 to day 5 (Fig. 11).
22 Note that the anomalous easterlies dominate over the equatorial Indian Ocean from day -25 to
23 day -15. At day -25, a positive OLR center (representing the suppressed convective phase of

1 MJO) is located in the EIO, while a negative OLR center (representing the enhanced convective
2 MJO phase) is located in the western equatorial Pacific. If the anomalous flow in the tropical
3 Indian Ocean is a direct Kelvin wave response to the positive heating in the western Pacific, one
4 would expect continuous easterly anomalies across the Pacific and Atlantic basin and Africa. As
5 one can see, the zonal wind anomaly is not continuous and is broken over the eastern equatorial
6 Pacific at both day -25 and day -20 (see ellipsoids in Fig. 11). At day -15, the positive heating is
7 so weak that westerly anomalies (rather than easterly anomalies) appear across the Pacific.
8 During the initiation period there is an opposite trend between the anomalous wind over the
9 Indian Ocean and the western Pacific heating anomaly. Whereas the local anomalous wind is
10 strengthened from day -25 to day -15, the heating weakens as it moves slowly eastward. At day
11 -15, the major branch of the MJO convection is confined to the west of the dateline. It is difficult
12 to argue that such a weak heating is able to exert an upstream impact on the initiation of new
13 MJO convection in the WIO. On the other hand, the strength and pattern of the anomalous wind
14 over the Indian Ocean are closely related to the negative heating anomaly over the EIO.
15 Therefore, Figure 11 presents observational evidence that the anomalous wind over the Indian
16 Ocean is a direct Rossby wave response to the suppressed MJO heating over the EIO.

17 To further support the downstream forcing argument, we plotted the longitude-time section
18 of the intraseasonal OLR and 850-hPa zonal wind anomalies averaged over 20°S-0°N (Fig. 12).
19 While the zonal wind anomaly shows a conventional circumnavigation feature around the global
20 tropics, the OLR anomaly exhibits a rather discontinuity characteristic, with a negative OLR
21 anomaly in the WIO (around 60°E) occurring earlier than that over Africa. A similar
22 discontinuity is found in the anomalous precipitation and lower-tropospheric specific humidity
23 fields (figure not shown).

1 The evidence above suggests that the MJO initiation could not arise from the continuous
2 eastward propagation of a preceding circumnavigating MJO mode; rather it arises from the setup
3 of local potential instability induced by low-tropospheric circulation and moisture changes
4 associated with the downstream forcing of a suppressed-phase MJO over the EIO.

5 The effect of the circumnavigating MJO mode can be further assessed through a set of
6 idealized numerical experiments. To evaluate the role of the circumnavigating waves on the MJO,
7 in the EXP_TA run, the eastward-propagating intraseasonal signal is greatly suppressed over the
8 tropical Atlantic. Figure 13 shows the power spectrum of simulated intraseasonal OLR fields
9 from both the control run and the EXP_TA run based on a wavenumber-frequency analysis. The
10 magnitudes of averaged 20-90-day OLR spectrum for zonal wavenumber 1 in both the
11 experiments are quite similar. This points out that the overall eastward-propagating MJO
12 variance has little change even though the circumnavigating MJO mode is greatly suppressed.

13 To examine whether or not the suppression of the circumnavigating mode affects the
14 convection initiation over the WIO, we plotted the variance map of 20-90-day filtered OLR
15 fields for both the control and EXP_TA cases (Fig. 14). It is interesting to note that the averaged
16 value of MJO variance in the initiation region is $660 \text{ W}^2\text{m}^{-4}$ in the EXP_TA run, which is slightly
17 larger than that ($590 \text{ W}^2\text{m}^{-4}$) in the control run. Thus the numerical simulations support the
18 notion that the circumnavigating mode has little contribution to the initiation of MJO convection
19 over the WIO.

20

21 **6. Mid-latitude wave activity flux and barotropic energy conversion**

1 It has been shown from previous case studies (e.g., Hsu et al. 1990; Ray et al. 2009) that the
 2 mid-latitude perturbations may contribute to MJO initiation over the WIO. To examine this
 3 possible mid-latitude impact, we plotted the upper tropospheric (200 hPa) geopotential height
 4 anomaly pattern during the initiation period (Fig. 15). Note that the geopotential height anomaly
 5 displays a wave train pattern, with high pressure centers located southeast of South of America
 6 and southeast of Africa, and low-pressure centers in between and to the east of Madagascar.

7 To illustrate wave energy dispersion characteristics, we calculated a phase-independent
 8 wave activity flux following Takaya and Nakamura (2001),

$$9 \quad W = \frac{1}{2|\bar{u}|} \left(\begin{array}{l} \bar{u}(\psi_x'^2 - \psi' \psi_{xx}') + \bar{v}(\psi_x' \psi_y' - \psi' \psi_{xy}') \\ \bar{u}(\psi_x' \psi_y' - \psi' \psi_{xy}') + \bar{v}(\psi_y'^2 - \psi' \psi_{yy}') \end{array} \right) \quad (5)$$

10 where a bar and a prime denote the LFBS and the intraseasonal anomaly, W represents the
 11 horizontal wave activity flux, u and v are zonal and meridional wind velocity, and ψ denotes
 12 the streamfunction.

13 The so-calculated 200-hPa wave activity flux vector and the flux convergence during the
 14 initiation period (from day -25 to day -15) are plotted in Fig. 15. Over most of mid-latitude in the
 15 Southern Hemisphere, there are pronounced eastward wave activity fluxes, indicating that the
 16 Rossby wave energy propagates eastward. The eastward wave activity fluxes turn northward and
 17 converge onto the tropical Indian Ocean between 10°S-30°S. The wave flux convergence implies
 18 that the wave energy is accumulated over the region. A similar wave activity flux feature is also
 19 found in the lower-tropospheric geopotential height anomaly field (figure not shown), indicating
 20 that the Rossby wave train has an equivalent barotropic structure. Thus, SH mid-latitude Rossby

1 wave perturbations may trigger the MJO initiation in the tropical Indian Ocean through wave
2 energy accumulation.

3 The role of the mid-latitude forcing effect is further examined through idealized numerical
4 experiments. As described in section 2, the EXP_NS experiment was designed to eliminate the
5 mid-latitude influence on the MJO. By comparing the intraseasonal OLR spectrum in the control
6 and EXP_NS run (Fig. 16a and b), one can see that the intraseasonal variability in the tropics
7 weakens significantly. For example, the averaged spectrum for zonal wavenumber 1 and
8 20-90-day period is reduced by 45%. Thus the numerical result confirms that the remote forcing
9 from mid-latitudes is important in affecting the overall tropical MJO variance.

10 To understand the relative role of the SH and NH mid-latitude forcing effect, we conducted
11 two additional experiments termed as “EXP_SH” and “EXP_NH” respectively. In EXP_SH
12 (EXP_NH) run, we blocked the equatorward propagation of SH (NH) mid-latitude waves.
13 Compared to the control run, the averaged spectrum for zonal wavenumber 1 and 20-90-day
14 period in the EXP_SH (EXP_NH) is reduced by 42% (7%) (Fig. 16c and d). The sensitivity
15 experiments result indicate that most of the spectrum reduction in EXP_NS is attributed to SH
16 wave blocking. Therefore, the remote forcing from mid-latitude SH is crucial for triggering
17 tropical convection associated with MJO.

18 In addition to the energy accumulation process, the intraseasonal perturbation in the WIO
19 may obtain energy from the mean flow. This local energy transfer process is through barotropic
20 energy conversion. According to Hoskins et al. (1983) and Simmons et al. (1983), the barotropic
21 energy conversion may be calculated based on the following formula:

$$22 \quad CK = \frac{v'^2 - u'^2}{2} \left(\frac{\partial \bar{u}}{\partial x} - \frac{\partial \bar{v}}{\partial y} \right) - u'v' \left(\frac{\partial \bar{u}}{\partial y} + \frac{\partial \bar{v}}{\partial x} \right) \quad (6)$$

1 where a bar denotes the climatologic seasonal mean quantity, and a prime denotes the
2 intraseasonal anomaly. A positive value of CK indicates an energy conversion from the mean
3 flow to the perturbation, that is, the MJO gains kinetic energy from the mean flow.

4 Figure 17 shows the calculated barotropic energy conversion field averaged over the
5 northern winter season. A positive CK is concentrated in the southern Indian Ocean (around
6 20°S - 0°N). This indicates that the barotropic energy conversion due to the MJO-mean flow
7 interaction always contributes positively to the initiation and growth of the intraseasonal
8 perturbations over the Indian Ocean.

9

10 **7. Conclusion and discussion**

11 The precursor signals associated with MJO convection initiation over the western equatorial
12 Indian Ocean in boreal winter are examined based on the diagnosis of observational and ERA-40
13 reanalysis data. A marked increase of the lower-tropospheric moisture and temperature occurs
14 5-10 days prior to the convection initiation. The increase of the low-tropospheric moisture and
15 temperature enhances lower-tropospheric equivalent potential temperature and moist static
16 energy, which help set up a convectively more unstable stratification and eventually lead to the
17 onset of the MJO convection over the WIO.

18 The diagnosis of the lower-tropospheric moisture budget shows that the moisture increase
19 prior to the MJO initiation is caused primarily by anomalous horizontal advection. The vertical
20 advection (associated with anomalous descending motion and lower-tropospheric divergence)
21 plays a negative role. A further separation of the mean and perturbation motion shows that the
22 horizontal moisture advection is mainly attributed to the advection of the mean specific humidity

1 by the MJO flow. The diagnosis of the lower-tropospheric heat budget shows that the
2 temperature increase prior to the MJO initiation is primarily caused by the adiabatic warming
3 associated with anomalous descending motion and the anomalous horizontal advection of the
4 mean temperature by the MJO flow.

5 The moisture and heat budget analyses above indicate that the moisture and temperature
6 precursor signals are primary induced by anomalous winds. Whether or not the anomalous local
7 circulation is due to the upstream forcing of the circumnavigating MJO mode or a downstream
8 forcing over the EIO is investigated through the analysis of both the observational data and
9 idealized numerical experiment output. While the equatorial zonal wind anomaly shows more
10 smooth eastward phase propagation around the globe, the OLR, precipitation and
11 lower-tropospheric specific humidity anomalies exhibit a rather discontinuity characteristic, with
12 the convection initiation over the WIO occurring earlier than that over Africa. Prior to the
13 initiation, the major branch of the preceding MJO convection is confined to the west of the
14 dateline. In response to the heating, anomalous easterlies appear to the east of the heating center.
15 However, the easterly anomaly does not extend all the way to the WIO. It is discontinuous over
16 the eastern equatorial Pacific (Fig. 11). Thus it is unlikely that the wind anomaly over the Indian
17 Ocean is affected by the positive heating anomaly over the western Pacific. It is found that the
18 local wind anomaly is more closely linked to the forcing of a negative heating anomaly over the
19 EIO, suggesting a downstream Rossby wave forcing scenario. An idealized numerical
20 experiment with the circumnavigating MJO mode being suppressed supports this claim.
21 Compared to the control experiment, the MJO variance in the idealized experiment does not
22 change much. The observational and modeling results imply that the local precursor signals are

1 mainly set up by the preceding suppressed-phase MJO over the EIO in the form of a Rossby
2 wave response.

3 Our analysis suggests that the energy propagation and accumulation of SH mid-latitude
4 Rossby waves is another possible triggering mechanism for MJO initiation over the WIO. A
5 calculation of the Rossby wave activity flux shows that there is wave energy accumulation over
6 the MJO initiation region. The possible SH mid-latitude impact on the tropical intraseasonal
7 variability is further supported by an idealized numerical experiment that prohibits the energy
8 and phase propagation of SH mid-latitude perturbations toward the tropics. The NH mid-latitude
9 impact supported by sensitivity experiments is modulating the MJO period.

10 It is found that positive barotropic energy conversion appears in the MJO initiation region.
11 This implies that the seasonal mean flow may provide kinetic energy to MJO disturbance and
12 thus may be responsible for the initiation and development of intraseasonal perturbations over
13 the tropical Indian Ocean.

14 The result presented from this study is different from Kikuchi and Takayabu (2003, KT
15 hereafter), who emphasized the role of circumnavigating signal in MJO initiation. Note that KT
16 constructed the MJO signal using extended EOF patterns in a global tropics domain. While this
17 methodology can capture dominant large-scale propagation features, it greatly underestimates (or
18 smoothes out) regional scale features associated with MJO convection initiation in WIO. For
19 instance, according to KT's Fig. 5, the convection initiation appears at 60°E around $t=4$. Before
20 this initiation time, low-level wind is a pronounced westerly anomaly, which is opposite to our
21 result (we noted significant easterly anomaly signals prior to the initiation). Secondly, total
22 precipitable water (TPW) used in KT is a vertically-integrated variable, which is approximately
23 in phase with the precipitation anomaly (see KT's Fig. 5); thus the TPW does not lead the

1 convection. However, in the current analysis we noted that a key precursor signal is
2 lower-tropospheric specific humidity, which leads the convection anomaly by 5-10 days.

3 One issue related to the MJO initiation is whether the local forcing in the tropics and the
4 remote forcing from mid-latitudes are independent. In the current work we examined the
5 composite evolution patterns based on the 20-yr analysis period (total 55 cases). Our composite
6 patterns show that both the internal tropical process and the external mid-latitude forcing
7 processes happened during the initiation period (day -25 to day -15). However, for each
8 individual case, the two processes may occur on the same time and independently. From a
9 physical mechanism point of view, the two processes are very different. One emphasizes
10 low-level moisture advection process, and the other emphasizes upper-tropospheric Rossby wave
11 energy propagation and accumulation. The former may trigger the convection through the
12 gradual setup of a convectively unstable stratification, whereas the latter may trigger MJO
13 perturbation through upper-tropospheric potential vorticity (PV) invasion. A related issue is the
14 cause of irregularity of MJO. The timing between MJO events is highly variable, whereas the
15 postulated downstream Rossby wave response would seem to have a more tightly bound
16 periodicity. Thus it is reasonable to hypothesize that the horizontal advection of mean specific
17 humidity by MJO flow keep moistening lower troposphere in the WIO until a trigger (from
18 extratropics perhaps) comes along. In this case, low-level moistening is a necessary but not a
19 sufficient condition for MJO initiation. On the other hand, not all individual MJO events may
20 experience a gradual moistening before initiation. Thus a further study is needed to identify the
21 relative roles of the tropical and extratropical triggering processes. In the subsequent study we
22 will examine each of individual MJO events (from both the observational and model data) to
23 reveal the relationship between the tropical and extratropical forcing.

1 Another issue is how the current analysis result depends on data. In this study we used the
2 ERA-40 reanalysis data. A preliminary sensitivity test using different datasets such as NCEP
3 Climate Forecast System Reanalysis (CFSR) and NASA Modern Era Retrospective-Analysis for
4 Research and Applications (MERRA) shows that precursor signals obtained in the present study
5 are robust across different datasets. This adds confidence to the present observational analysis.

17 (θ_e) and moist static energy (MSE) fields averaged over the MJO initiation region (50° - 70° E,
18 20° S- 0° N).

19 Fig. 5 (Top) Evolutions of the potential instability parameter $\Delta\theta_e$ (green curve), lower-
20 tropospheric θ_e (θ_{eL} , averaged over 700-1000hPa, blue curve), and middle-tropospheric θ_e (θ_{eM} ,
21 averaged over 300-400hPa, red curve). (Bottom) Change of the θ_{eL} (unit: K) from day -25 to day
22 -15 (red bar) and contributions to the θ_{eL} change due to lower-tropospheric temperature (green

1 bar) and specific humidity (blue bar) variations.

2 Fig. 6 (a) 1000hPa-700 hPa integrated intraseasonal moisture budget terms averaged during the
3 period of day -25 to day -15 over 50°-70°E, 20°S-0°N. From left to right: observed specific
4 humidity tendency, horizontal moisture advection, vertical moisture advection, apparent moisture
5 source, and sum of the last three terms. (b) Individual components of the horizontal moisture
6 advection term. (c) Vertical profiles of the apparent moisture source term.

7 Fig. 7 Vertically integrated (1000hPa-700hPa) intraseasonal wind and LFBS specific humidity
8 fields (top) and vertically integrated intraseasonal specific humidity and LBFS wind fields
9 (bottom) averaged during the initiation period (day -25 to day -15).

10 Fig. 8 (a) Vertically-integrated (1000hPa-700hPa) intraseasonal temperature budget terms during
11 the initiation period (from day -25 to day -15) over 50°-70°E, 20°S-0°N. (b) Individual
12 components of the horizontal temperature advection. (c) Individual components of the adiabatic

13 term (from left to right): $(\bar{\omega} \frac{R\bar{T}}{c_p p} - \bar{\omega} \frac{\partial \bar{T}}{\partial p})'$, $(\bar{\omega} \frac{RT'}{c_p p} - \bar{\omega} \frac{\partial T'}{\partial p})'$, $(\bar{\omega} \frac{RT^*}{c_p p} - \bar{\omega} \frac{\partial T^*}{\partial p})'$, $(\omega' \frac{R\bar{T}}{c_p p} - \omega' \frac{\partial \bar{T}}{\partial p})'$,

14 $(\omega' \frac{RT'}{c_p p} - \omega' \frac{\partial T'}{\partial p})'$, $(\omega' \frac{RT^*}{c_p p} - \omega' \frac{\partial T^*}{\partial p})'$, $(\omega^* \frac{R\bar{T}}{c_p p} - \omega^* \frac{\partial \bar{T}}{\partial p})'$, $(\omega^* \frac{RT'}{c_p p} - \omega^* \frac{\partial T'}{\partial p})'$, $(\omega^* \frac{RT^*}{c_p p} - \omega^* \frac{\partial T^*}{\partial p})'$.

15 Fig. 9 Vertically integrated (1000hPa-700hPa) intraseasonal wind and LFBS temperature fields
16 averaged during the initiation period (day -25 to day -15).

17 Fig. 10 Schematic diagrams illustrating a) an upstream forcing scenario in which a positive MJO
18 heating in the western Pacific may induce an anomalous easterly over the WIO through Kelvin
19 wave response and b) a downstream forcing scenario in which a negative heating anomaly
20 associated with suppressed-phase MJO may induce twin-gyre circulation in the tropical Indian

1 Ocean through Rossby wave response.

2 Fig. 11 Evolution of the composite OLR (color; unit: Wm^{-2}) and 850-hPa wind (vector; unit: ms^{-1})
3 patterns from day -25 to day 5 at an interval of 5 days.

4 Fig. 12 Time-longitude section of the composite OLR (color; unit: Wm^{-2}) and 850hPa zonal wind
5 (contour; unit: ms^{-1}) anomalies averaged along 20°S - 0°N .

6 Fig. 13 The wavenumber-frequency spectra (unit: W^2m^{-4}) of the intraseasonal OLR anomaly
7 derived from the 20-yr simulation of the Control and EXP_TA experiments. The spectrum
8 analysis was done for a limited domain over (40°E - 180°E , 20°N - 20°S).

9 Fig. 14 Horizontal distribution of 20-90-day filtered OLR variance (unit: W^2m^{-4}) in boreal winter
10 derived from the Control and EXP_TA experiments.

11 Fig. 15 20-90-day filtered observed geopotential height anomaly (contour, unit: m^2s^{-2}), Rossby
12 wave activity flux (vector, unit: m^2s^{-2}) and wave flux divergence (color, unit: 10^{-5}ms^{-2} , only
13 negative values are shaded over the Indian Ocean) at 200 hPa during the initiation period from
14 day -25 to day -15.

15 Fig. 16 Same as Fig. 13 except for the Control, EXP_NS, EXP_SH and EXP_NH experiments.

16 Fig. 17 Horizontal distribution of the 850-hPa barotropic energy conversion field (color, unit:
17 $10^{-5} \text{m}^2\text{s}^{-3}$) and the seasonal mean 850-hPa wind field (vector, unit: ms^{-1}).

2 Table 1. List of Numerical Experiments

Experiment	Description	Purpose
Control	ECHAM4 atmosphere only, forced by the climatological monthly SST	MJO evaluation; Provide controlled annual cycle conditions for other experiments
EXP_TA	Relaxed to the annual cycle derived from the control run over the tropical Atlantic	To evaluate the role of the circumnavigating MJO mode
EXP_NS	Relaxed to the annual cycle derived from the control run over 20°S-30°S and 20°N-30°N	To evaluate the role of the mid-latitude influence
EXP_SH	Relaxed to the annual cycle derived from the control run over 20°S-30°S	To evaluate the role of the SH mid-latitude influence
EXP_NH	Relaxed to the annual cycle derived from the control run over 20°N-30°N	To evaluate the role of the NH mid-latitude influence
